1 Basics: events, time, and traces

Every contract specifies a time unit; it is the smallest unit of time that one writes constraints about or does arithmetic with. We expect it will most often be days. A time stamp is a natural number that we think of as being in units time unit.

An event is composed of an action, a role, a time stamp, and optionally some parameters (but parameters will not be introduced until Section 4). The actions and roles are fixed finite sets. In this first version of L4, there is exactly one participant of each role.

All events are modelled as actions, and a special role Env is used to model events that have no agent (role).

A trace is a sequence of events. The time stamps of the events must be nondecreasing. Thus, within the smallest unit of time, any number of events can happen; however, they are always strictly ordered. The idea here is that we want events to be strictly ordered for simplicity and to minimize the size of the space of execution traces, but if we made the time stamps strictly increasing, we would need to be working at a level of granularity for time that is at least one level smaller than the smallest unit of time that would appear in an informal version of the contract (at least when time unit = days, since contracts that use days as their minimum unit generally do not require that all events happen on different days).

A contract has a fixed finite number of states, one of which is designated the start state, and which includes at least the following:

- fulfilled
- breach$_X$ for each nonempty subset X of the roles. There is also an action breaches$_X$ for each such X, which is used in the formal execution semantics, but is unlikely to be used directly in a language for contracts.

Between any two events in a trace, the contract is in some global state which consists of at least a time stamp for the current time and a state (in Section 3, global variables will be added).

A contract has a finite directed edge-labeled multigraph[1] which we might call its skeleton; the nodes are the states, and each directed edge, which we will call a transition, is labeled with an action. Some notation:

- For r a role, an r-transition is a transition whose role is r.
- For a an action, an a-action (a-transition) is an event (transition) whose action is a.
- For s a state, the incoming s-transitions (outgoing s-transitions) are the edges coming into (going out of) s.

Every transition is one of the following three types. They will be explained in more detail in the next section.

- A may next transition is a permission.
- A relievable must next transition will be the most-used kind of obligation.
- A must next transition is the strongest possible obligation.

[1] By this I mean there may be multiple edges from one node to another, but they must have different labels.

Since the environment Env cannot breach a contract or be *obligated* to do anything, no Env-transition can be a must next transition or a relievable must next transition. That completes the definition of the finite directed graph skeleton of a contract.

2 Simple Contracts

We obtain the first complete, but limited, model of contracts, called simple contracts, by elaborating on the definitions from the previous section.

Each transition τ is associated with a transition guard $\mathsf{transGuard}_\tau(\cdot)$. In the case of simple contracts, it is just a relation on time stamps. A transition τ is enabled upon entering a global state with time stamp t iff $\mathsf{transGuard}_\tau(t)$ is true.[2]

The transition guards must satisfy the following conditions, which would be statically verified in a language for simple contracts:

unambiguous absolute obligation condition: For every time stamp t, if some must next transition evaluates to true (at t) then every other transition guard evaluates to false (at t).

choiceless relievable obligations condition: For every role r and time stamp t, if one of r's relievable must next transitions evaluates to true (at t) then any other relievable must next transitions for r evaluate to false (at t).

We say that a transition τ and an event $E = \langle a, r, t \rangle$ are compatible iff they have the same action a and the same role r. This definition will be modified in Section 3 when we add event parameters.

Each transition τ is also associated with a deadline function $\mathsf{deadline}_\tau(\cdot)$, which gives a time stamp for a deadline when:

- an enabled may next transition (a kind of permission) expires.
- an enabled must next transition (the strong form of obligation) causes a breach by role_τ[3] if a compatible event has not been performed by the deadline.

[2]Currently, LSM examples are written assuming the transition guards of a state s's transitions get evaluated only once upon entering the state. It would also be reasonable to guess that they get evaluated once per time unit while the contract is in that state. This is not ideal.

[3]Which recall, in this formal model means a transition to the state $\mathsf{breach}_{\{\mathsf{role}_\tau\}}$

- an enabled relievable must next transition (the weak form of obligation) causes a possibly-joint breach by role_τ if a compatible event has not been performed by the deadline **and** no other permitted event is performed by the deadline.

For simple contracts, a deadline function is just a function from time stamps to timeunit $\cup$ timestamps. If d is such a function, and a state is entered at time stamp t, then:

- If $d(t) \in$ timestamps, the deadline is $d(t)$.
- If $d(t) \in$ timeunit, the deadline is $t + d(t)$.

That completes the definition of simple contract. In the next section, we give the complete definition of how a simple contract executes on a trace.

2.1 Execution

A simple contract of course starts in its start state. Let $E_1, E_2, \ldots$ be a finite or infinite trace (recall: a sequence of events), as defined in Section 1. Let G_i be the global state that follows E_i for each i.

G_0 is $\langle \mathsf{startstate}, 0 \rangle$.

Let $i \geq 0$, and assume execution is defined up to entering G_i. To reduce notational clutter, let us use the aliases:

$$G = \langle s, t \rangle = G_i \qquad E = E_i \qquad G' = \langle s', t' \rangle = G_{i+1}$$

Case 1: There is some enabled must next transition τ in G. If there is any other enabled transition, then this contract (not just this trace) violates the unambiguous absolute obligation condition, and so is invalid.[4]

(a) If E is compatible with τ and E happens within τ's deadline, then the next state must be target_τ.[5] This means A fulfilled the obligation created by τ.

(b) Otherwise, Otherwise, If E is not compatible with τ then role_τ solely breaches the contract. We specify that E must be

(c) If E is compatible with τ and E happens after τ's deadline, then role_τ solely breaches the contract.

[4] Recall that a language (tool) for simple contracts will verify that such a thing can't happen.

[5] i.e. if $t' \leq \mathsf{deadline}_\tau(t)$ then $s' = \mathsf{target}_\tau$.

Todo: Cases (b) and (c) should be joined. They must be transitions to $\mathsf{breach}_{\mathsf{role}_\tau}$ at time 1 after the deadline.

Case 2: There is no enabled must next transition τ in G. From the enabled may next transitions of s in G, compute the deadline for each, and discard the transitions whose deadline has passed by the time E happens;[6] let T_p be the resulting set of transitions. From the set of enabled relievable must next transitions in G, compute the deadline for each, and discard the transitions whose deadline is not minimal within that set; let T_o be the resulting set. Then A must be compatible with one of the transitions in that filtered set.

3 Infinite state: Global Variables and Event Parameters

Add to the definition of contract:

- A fixed finite set of typed global variables. The global variables are ordered, so we may describe their collective types as a single tuple $\mathsf{GVarTypes}$.
  Add to the definition of global state an assignment of values to the global variables.
- An assignment of types to the actions. This allows events to have parameters. We refer to such a type as an action-parameters domain, and the specific action-parameters domain for action a is $\mathsf{ParamTypes}_a$.

events receive the following modifications:

- Each action a additionally has a global variables transform, denoted $\mathsf{transform}_a$, which is a function from $\mathsf{GVarTypes} \times \mathsf{ParamTypes}_a$ to $\mathsf{GVarTypes}$.
- And the definition of a-transition is extended:
  - The transition guard attached to an a-transition may now depend on the values of the global variables; i.e. it is now a relation on timestamp $\times$ $\mathsf{GVarTypes}$.
  - Each a-transition additionally gets an action-schema constructor called $\mathsf{actionSchema}_a$. This is a function from $\mathsf{GVarTypes}$ to a set of events all of whose action is a. We call such a set of actions an action schema.

The unambiguous absolute obligation condition is updated: Let T be the set of transition guards of the must next transitions of some state s. For any global

[6] i.e. discard τ if $\mathsf{deadline}_\tau(t) > t'$.

variables assignment σ and time stamp t, at most one of the transition guards in T evaluates to true. **Todo**[7]

Note (probably to move to some other section or document): it will often be the case in a language for contracts that we simultaneously define an action a and a state JH_a (for "a Just Happened", to fit its literal meaning). In this case, the incoming JH_a-transitions are exactly the set of a-transitions. As a convenience, a language for contracts will allow the outgoing JH_a-transitions to depend directly on a's parameters (that is, for the transition guard and action-schema constructor to depend on a's parameters). This is merely a convenience because, as we will see when we define execution, one can achieve the same effect by introducing new global variables that are only used by a and JH_a; a uses $\mathsf{transform}_a$ (recall, its global variables transform) to save its parameter values to those new global variables, so that the outgoing JH_a-transitions can then refer to them.

3.1 Execution

4 May-Later and Must-Later

This section does not actually change the definition of contract. Instead, it defines, essentially, an often-useful contract structure that is likely to be supported with custom syntax in a language for contracts.

We have so far been noncommittal about what types are available for global variables and action-parameters domains. We will see later that the types strongly affect expressivity. As a special case, the reader should convince themselves that any contract that uses only boolean (or other finite domain) types can be simulated by a simple contract (using a much larger number of states).

[7] Later will be: For any global variables assignment σ and time stamp t that makes s's precondition true, at most one of the transition guards in T evaluates to true.
